## ORIGINAL PAPER

# Genetic diversity and parasite prevalence in two species of bumblebee

**Abstract** Many bumblebee species have been suffering from significant declines across their ranges in the Northern Hemisphere over the last few decades. The remaining populations of the rare species are now often isolated due to habitat fragmentation and have reduced levels of genetic diversity. The persistence of these populations may be threatened by inbreeding depression, which may result in a higher susceptibility to parasites. Here we investigate the relationship between genetic diversity and prevalence of the parasitic mite Locustacarus buchneri in bumblebees, using the previously-studied system of Bombus muscorum and Bombus jonellus in the Western Isles of Scotland. We recorded L. buchneri prevalence in 17 populations of B. muscorum and 13 populations of B. jonellus and related the results to levels of heterozygosity. For B. muscorum, we found that prevalence of the mite was higher in populations with lower genetic diversity but there was no such relationship in the more genetically diverse B. jonellus. In contrast to population-level measures of genetic diversity, the heterozygosity of individual bees was not correlated with infection status. We suggest population-level genetic homogeneity may facilitate parasite transmission and elevate prevalence, with potential consequences for population persistence.

**Keywords** Inbreeding · Social insects · Heterozygosity · Disease

# Introduction

The role bumblebees have as pollinators makes them a vital component of ecosystems and also gives them great economic value. Over recent decades many bumblebee species have been declining across their range in the Northern hemisphere, predominantly due to the intensification of agriculture and the resultant loss of habitats (Goulson et al. 2008; Williams and Osborne 2009). These declines have been particularly severe in the UK where 3 of the 27 native species have become extinct and 10 species have undergone severe range contractions (Goulson 2010). The remaining populations of the rarer species have become isolated in habitat patches where suitable forage and sites for nesting still exist. There are instances of these populations going extinct, despite the continuing presence of good habitat. For example, Wicken Fen in central England supported 14 species of Bombus in the 1920s but by 1978 only six remained (Williams 1986).

In order to implement the appropriate conservation strategies for bumblebees it is important to understand what is driving these remaining populations to extinction. Research has suggested that genetic factors might have a role; rare species with fragmented populations, such as *B. sylvarum* and *B. muscorum* in the UK and *B. occidentalis* and *B. pensylvanicus* in North American have much lower

genetic diversity than common, widespread species such as B. terrestris and B. pascuorum in the UK and B. bifarius and B. impatiens in North America (Ellis et al. 2006; Darvill et al. 2006; Cameron et al. 2011; Lozier et al. 2011). Detailed study of the genetic diversity and population structure of B. muscorum has provided further information. B. muscorum has become rare across its range in the UK and is now predominantly found in the Western Isles of Scotland. Darvill et al. (2006) found that the more isolated island populations of B. muscorum were genetically differentiated from those closer to the mainland and had substantially reduced genetic diversity. These studies suggest that habitat fragmentation and population isolation have led to a loss of genetic diversity in rare species of bumblebees. If the populations with reduced levels of genetic diversity also have lower fitness, inbreeding depression may be occurring. This might be the mechanism driving these populations towards extinction, as has been demonstrated in other invertebrate species (Saccheri et al. 1998; Reed et al. 2007).

One form of inbreeding depression, which may lead to an increased extinction risk, is higher susceptibility to parasitism (de Castro and Bolker 2005). Increased homozygosity can increase both the prevalence of parasites at the population level and susceptibility to parasites at the individual level (Frankham et al. 2010). At the population level, the more genetic diversity present, the more likely it is that some individuals can resist a pathogen. If this genetic diversity is lost due to inbreeding, pathogen epidemics may spread more efficiently in the genetically homogenous population. Previous work by Whitehorn et al. (2011) has supported this theory, revealing a negative correlation between genetic diversity of island populations of B. muscorum, and prevalence of the intestinal microparasite Crithidia bombi. Further support comes from North America, where declining bumblebee populations have lower levels of genetic diversity and a significantly higher prevalence of the pathogen N. bombi compared to stable bumblebee populations (Cameron et al. 2011). Similar relationships have been found in other invertebrates (e.g. Ebert et al. 2007), but not universally (Trouve et al. 2003; Field et al. 2007).

Experimental work with Drosophila in the laboratory suggests that inbreeding can decrease the immunity of invertebrates at the individual level through the loss of specific resistance alleles (Spielman et al. 2004) or reduced defensive behaviour (Luong et al. 2007). Knowledge of the individual inbreeding co-efficient (*f*) is informative when establishing whether such relationships exist between inbreeding and parasite susceptibility at the level of the individual. This is calculated using detailed pedigree information, but this is rarely available for wild populations (Marshall et al. 2002). As an alternative, microsatellites

This study aims to further investigate the relationship between genetic diversity and parasitism in bumblebees. We consider two bumblebee species, B. muscorum and B. jonellus, that live sympatrically in the Western Isles of Scotland but have different levels of genetic diversity. Investigating their levels of parasitism allows us to compare the impacts that inbreeding and population differentiation have on parasites. Bombus muscorum belongs to the subgenus Thoracobombus and is considered threatened. It has been placed on the UK Biodiversity Action Plan (UKBAP) along with three other species belonging to its subgenus. Bombus jonellus is a member of the subgenus Pyrobombus and has a widespread but local distribution and is not thought to be threatened (Benton 2006). Darvill et al. (2010) found that the two species differed significantly in overall heterozygosity with B. muscorum exhibiting much lower genetic diversity. B. muscorum also shows markedly higher population structuring and isolation by distance than B. jonellus ( $\theta = 0.13$  compared to  $\theta = 0.034$ ). B. jonellus has evidently retained genetic cohesion over greater distances and it was estimated that they are able to disperse >50 km relatively frequently. In contrast, B. muscorum were estimated to disperse >8 km only infrequently and the species also showed an increased frequency of population bottlenecks (Darvill et al. 2010). These differences in dispersal abilities suggest that B. muscorum is more susceptible to population isolation due to habitat fragmentation.

This study tests how genetic diversity differences between host species, populations and individuals impact on parasite prevalence. To do this we quantify the prevalence of the tracheal mite, *Locustacarus buchneri*, in the *B. muscorum* and *B. jonellus* individuals collected by Darvill et al. (2010).

# Methods

During the summers of 2003–2005, individuals of *B. muscorum* and *B. jonellus* were collected from islands in the Inner and Outer Hebrides and stored in 100 % ethanol.

Table 1 Population means for host genetic diversity and parasite prevalence

|            | Longitude      | Latitude        | Island size (km <sup>2</sup> ) | Bombus muscorum |                                     |                  | Bombus jonellus             |                                     |                  |

The figures in parentheses are the standard errors for genetic diversity and the 95 % CI for parasite prevalence. Measures for heterozygosity ( $H_E$ ) are taken from Darvill et al. (2010)

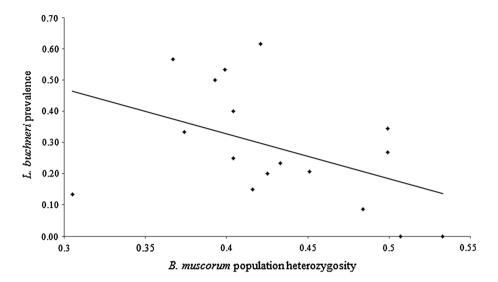

In a previously published study (Darvill et al. 2010), B. muscorum were genotyped at 8 microsatellite loci (B10, B11, B96, B118, B124, B126, B131, B132) and B. jonellus were also genotyped at 8 microsatellite loci (B10, B11, B96, B100, B121, B124, B126, B132). This gave each bee a measure of individual heterozygosity (the number of heterozygous loci divided by the number of genotyped loci). Tests for genotypic linkage disequilibrium and departure from Hardy-Weinberg equilibrium (HWE) were performed using GENEPOP version 3.4 (Raymond and Rousset 1995). Darvill et al. (2010) excluded loci with null alleles from their analysis. The presence of sisters within each population was checked using KINSHIP v 1.3.1 (Goodnight and Queller 1999), which assigned workers to colonies, allowing all but one representative from each nest to be removed. A measure of average (unbiased) heterozygosity (H<sub>E</sub>) for each population was also calculated using FSTAT and these figures are published in Darvill et al. (2010) (Table 1). For the present study, the width of the thorax of each bee was measured using electronic digital callipers and the bee's age was estimated by assessing the extent of wing wear, using a four point scale (modified from Mueller and Wolfmueller 1993). Each abdomen was then dissected in order to quantify the number of adult L. buchneri present.

#### Statistical analyses

All analyses were performed in R, version 2.15.3 (R Core Team 2013). Binomial generalised linear mixed effect models were used to investigate whether L. buchneri prevalence was influenced by the level of genetic diversity at the population level. Bombus muscorum and B. jonellus were analysed separately as island heterozygosity measures are different for the two species. Population-level heterozygosity, bee age (entered as a covariate with a four point scale), bee size (thorax width), sampling date (entered as a covariate, numbered continuously from June 1st through to September) and finally island area (as a proxy for bumblebee population size) were entered as fixed effects. Island and sampling year were entered as random factors and individual bee was the unit of replication. Binomial generalised linear mixed effect models were also used to analyse determinants of L. buchneri infection on an individual level. Fixed effects included: bumblebee species, individual heterozygosity, bee age, bee size and sampling date. Island and sampling year were entered as random factors. Models were fit with lmer in the lme4 package (ver. 1.0-4; Bates et al. 2013). Locustacarus buchneri infection intensity was also analysed, but no variables were found to significantly influence the number of adult mites

**Fig. 1** Relationship between *L. buchneri* prevalence and heterozygosity of the host populations. Each point represents an island population. Islands with high heterozygosity had significantly lower prevalence of *L. buchneri* (P = 0.005, table 2)

infecting the bees and so only the presence/absence results are presented here. All statistical tests were two-tailed and models were selected and simplified according to Akaike's Information Criterion (AIC). All two-way interactions were investigated, but as none of these were significant they are not reported here.

## Results

A total of 506 *B. muscorum* and 360 *B. jonellus* workers were dissected. The *B. muscorum* samples came from 17 island populations with a mean sample size of 29.8 (range 20–41) from each island. The *B. jonellus* samples came from 13 island populations with a mean sample size of 27.7 (range 18–30) from each island. The tracheal mite *L. buchneri* was present in 15 out of the 17 populations of *B. muscorum* and had an overall prevalence of 28 % in this species. The parasite was present in all populations of *B. jonellus* and had an overall prevalence of 39 % (Table 1). The mean number of mites per infected bee was 6.45 (range 1–68).

#### Population level results

There was a significant negative correlation between the prevalence of L. buchneri and B. muscorum population heterozygosity (Z=-2.78, P=0.005, Fig. 1). There was also a significant positive correlation between island size and L. buchneri prevalence (Z=3.15, P=0.002). There was no correlation between these two explanatory variables (r=-0.052, P=0.843). Sampling date significantly influenced L. buchneri infection; bees sampled later in the year were more likely to be infected (Z=2.33, P=0.020). Neither bee age nor size significantly affected L. buchneri infection in B. muscorum (Table 2). No

variable significantly influenced the overall prevalence of *L. buchneri* in *B. jonellus* populations (Table 2).

#### Individual level results

Bombus jonellus were more frequently infected with L. buchneri than B. muscorum ( $\chi^2 = 11.85$ , df = 1, P < 0.001). Bees sampled later in the season were more likely to be infected ( $\chi^2 = 5.51$ , df = 1, P = 0.019). Individual heterozygosity, bee age and size did not significantly predict whether bees were infected with L. buchneri (Table 3).

## Discussion

This study demonstrates that B. muscorum populations with lower levels of heterozygosity have higher prevalence of the tracheal mite L. buchneri. This builds on previous work by Whitehorn et al. (2011), who also studied Hebridean island populations of B. muscorum and found a significant negative relationship between parasite prevalence and host population genetic diversity in the gut trypanosome parasite Crithidia bombi. While this earlier study also examined L. buchneri, sample sizes were too low to detect meaningful biological relationships. Together with the recently discovered higher prevalence of N. bombi in US bumblebee populations that had reduced genetic diversity (Cameron et al. 2011), our results suggest a general relationship between parasite prevalence and genetic diversity in bumblebee populations. These findings support previous experimental work that found genetic heterogeneity within colonies to be negatively correlated with parasitic infections in social insects (Baer and Schmid-Hempel 2001; Hughes and Boomsma 2004; Seeley and Tarpy 2007).

**Table 2** Output of binomial generalised linear mixed effect models for the prevalence of L. buchneri in B. muscorum and B. jonellus populations

Although there was a population-level relationship between genetic diversity in B. muscorum and prevalence of L. buchneri, there was no such relationship between individual heterozygosity and infection. This could be because heterozygosity is not affecting susceptibility to parasites at an individual level, which is supported by Whitehorn et al. (2011) who found that individual immune measures were unaffected by genetic diversity. We hypothesise that the population-level effect that we observed results because particular parasite genotypes can spread to high prevalence in populations that lack genetic diversity at relevant pathogen susceptibility loci. Another explanation for the absence of a heterozygosity-infection association in individuals is that heterozygosity at the neutral markers genotyped may not be a good indicator of underlying inbreeding at the individual level. This is possibly due to the relatively small number of loci genotyped: a study by Slate and Pemberton (2002) concluded that, in order to reliably detect Heterozygosity Fitness Correlations (HFCs), a panel of ten or more microsatellite markers were needed. Other studies have also found that multi-locus heterozygosity is an unreliable predictor of individual genetic diversity at loci influencing fitness (for example, Hedrick et al. 2001; Pemberton 2004; Slate et al. 2004).

Relatively little research has been conducted on *L. buchneri* but limited data suggest that heavy infections

might be associated with lethargy and reduced foraging (Husband and Sinha 1970). In contrast, Acarapis woodi, the tracheal mite of honey bees Apis mellifera, has been studied in more detail. For example, experimental work has found that infection with A. woodi causes a reduction in the metabolic rate of individual bees and this may constrain activity, particularly in cool weather (Harrison et al. 2001). Additionally, a recent review (McMullan and Brown 2009) concluded that honey bee colonies infected with tracheal mites exhibit increased temperature dependent mortality. It is certainly possible that L. buchneri inflicts similar costs on bumblebees. Parasitic infection may also have indirect effects on fitness simply by stimulating the immune system (Brown et al. 2003; Bashir-Tanoli and Tinsley 2014) and L. buchneri infection does indeed trigger a melanisation response in the host's trachea (pers. obs.). Bumblebee colonies whose workers are immune challenged may have lower reproductive output, an effect that is exacerbated by harsh environmental conditions (Moret and Schmid-Hempel 2001, 2004). Therefore, parasitism is likely to exert fitness costs on the hosts and as prevalence is higher in less genetically diverse populations, it may increase their risk of extinction, as suggested by de Castro and Bolker (2005).

In contrast to the observations in B. muscorum, there was no relationship between the prevalence of L. buchneri and the genetic diversity of B. jonellus populations. This may be a result of the appreciably lower range in the measures of population heterozygosity (a range of only 0.019 compared to a range of 0.228 for B. muscorum), which may limit our ability to detect any influence that genetic diversity has on parasite prevalence. Interestingly, B. jonellus had consistently higher infection rates compared to B. muscorum, something its greater heterzyogosity would not lead us to expect. This could reflect the inability of the less genetically diverse B. muscorum to survive high levels of infection, meaning that high parasite prevalence was not observed. Alternatively, this observation may be due to an inter-specific difference in the parasitism rates of these two species, as such differences are commonly found in bumblebees (for example, Shykoff and Schmid-Hempel 1991; Korner and Schmid-Hempel 2005). The reasons

behind these differences remain unknown but are likely to relate to inter-specific variation in transmission opportunities, host genetics and parasite defence, environmental factors or parasite virulence.

In conclusion, this study has demonstrated that low genetic diversity in *B. muscorum* populations is associated with a higher prevalence of the tracheal mite *L. buchneri*. This supports theories that suggest parasite species can spread to higher prevalence in populations that are more genetically homogeneous. Therefore, the persistence of small, isolated populations of bumblebees may be threatened due to inbreeding and the associated effects on levels of parasitic infection.
